If, however, $Z^4$ be defined as the ratio between the pressure and the rate of volume displacement in the branch, the ratio of incident to transmitted energy can be shown to be:

$$\frac{Z_1 - \frac{\rho a}{2s} Z_2^2}{Z_1^2 + Z_2^2}$$

(2)

Consider a general case where the attached vessel has a point impedance, $Z_a$, this referring to a point just within the vessel. Denoting this by $Z_a$, the incident pressure $P$ at the opening can be expressed as:

$$\frac{p_c}{c} x + \frac{\rho a}{2s} x + Z_a x = P$$

(3)

From this it can be shown that the ratio of transmitted to incident energy is:

$$\frac{Z_a^2 + \left(\frac{ka}{c} Z_a\right)^2}{Z_a + \frac{\rho a}{2s}}$$

(4)

wherein $k$ is $2\pi$-wavelength and $c$ is the conductivity of the orifice. This is a general formula and has been tested in the case of a cylindrical resonator, a Helmholtz resonator and a simple orifice. In any branch in general, let there be two unknown quantities $Z_1$ and $Z_2$. It is possible to measure the ratio in (4) with conduits of various areas $s$ and thus to obtain the values of $Z_1$ and $Z_2$ separately assuming that $c$ is known.

THE ACTION OF A HELMHOLTZ RESONATOR IN A BRANCH LINE

G. W. STEWART

The general impression of a Helmholtz resonator is that, since its dissipation is small, its tuning is fairly sharp. It is noted with some surprise, therefore, that when used as a side branch in an acoustic transmission line it affects the transmission over a wide range of frequencies. The theory, derived from the general case in the preceding abstract has been checked by experiment with resonators of varying dimensions and the theory verified to a very satisfactory degree.
